Abstract

INTRODUCTION

Lipid composition of biomembranes vary greatly between different organelles and organism, and different lipid types interact with proteins in many different ways regulating their function [?]. Lipids may directly interact with proteins by specific binding sites or indirectly affect protein functions by altering membrane properties or charge [?]. Specific interactions with certain lipid headgroups are known to be essential for the function of several proteins [?]. However, it is not clear if the specific binding is driven by the differences in accessible conformational states between lipid types or by specific intermolecular interactions between lipids and proteins.

Differences between preferred conformations of different lipid types are observed in lipid crystal structures [1, 2], but lipids are not in solid state in biomembranes. On the other hand, NMR experiments enable detection of lipid headgroups in physiological liquid states also in cells [3–5]. These studies suggest that the glycerol backbone structures are largely similar irrespectively of the headgroup [3], glycerol backbone and headgroup structure and behaviour are similar in model membranes and in bacteria [3–5], and the headgroup structures are similar in PC, PE and PG lipids, while headgroup is more rigid in PS lipids [1, 6]. Attempts to resolve the conformational ensembles of lipid headgroup rely mainly on absolute values of C-H bond order parameters measured using ²H NMR [7–9]. However, appropriate models to interpret the experimental data have not been available and also the signs of the order parameters are required to fully capture the details in conformational ensembles [10, 11].

PE and PG lipids are most common lipids in bacteria [12]. Zwitterionic PE is the second most abundant glycerophospholipid in eukaryotic cells and has been related to the diseases

[13–15]. Anionic PG lipids are less abundant, but is also proposed to be fundamental for terrestrial life [16]. PE and PG affect membrane protein functionality [17] and bind to various proteins [18]. PE headgroup is also prone for negative membrane curvature and causes membrane fusion [14, 19]. Therefore, the PE and PG headgroup structures play probably essential roles in many biological processes.

Derivation of different lipid headgroup conformational ensembles in liquid state has been inconclusive due to lack of suitable experimental data and tools to interpret the conformational ensembles.

Besides the structure, also ion binding may regulate biophysical activity of especially negatively charged lipid headgroups [5]. Monovalent cation (except Lithium) binding to zwitterionic PC and anionic PS headgroups is very weak, while multivalent ion binding is stronger but still weak [20–24]. The ion binding affinity data for PE is more scarce [25], but large differences to PC would be surprising. Negatively charged lipids are suggested to bear same cation binding constants than zwitterionic lipids, but the amount of bound ions to negatively charged membranes would still be larger because the concentration of cations in the vicinity of membranes would be higher [5]. On the other hand, anionic PS lipids are proposed chelate with calcium ions [26–28]. In simulations, the cation binding affinity to PC and PS membranes is typically overestimated [23, 24], which can be improved by applying the ECC to the partial charges of the force fields [29, 30].

Here, we use open collaboration and order parameters of glycerol backbone and headgroup to evaluate the accuracy of PE and PG headgroup structures, and the cation binding affinity to anionic membranes containing PG lipids in the current MD simulation force fields. The force field giving the best

description for glycerol backbone and headgroup structures of PC, PS, PG and PE headgroups (CHARMM36) reproduces the essential differences in order parameters between these headgroups, and therefore enables the analysis of structural differences between the headgroups.

METHODS

Experimental C–H bond order parameters

The headgroup and glycerol backbone C–H bond order parameter magnitudes and signs of POPE and POPG were determined by measuring the chemical-shift resolved dipolar splittings with a R-type Proton Detected Local Field (R-PDLF) experiment [31] and S-DROSS experiments [32] using natural abundance ^{13}C solid state NMR spectroscopy as described previously [33, 34]. POPE and POPG powder were purchased from Avanti polar lipids. The NMR experiments were identical to our previous work [24]. **1. Is this enough and correct, or should we repeat some methods from the NMRLipidsIVps paper?** The POPE experiments were recorded at 310 K and POPG experiments at 298 K, where the bilayers are in the liquid disordered phase [35].

Absolute values of the headgroup and glycerol backbone order parameters from PE and PG lipids are measured previously using ^2H NMR [3, 6, 36, 37]. Because also the order parameter signs bear essential information about the lipid structures [10, 11], we measured the magnitudes and signs of POPE and POPG C–H bond headgroup and glycerol backbone order parameter in liquid phase using the 2D-RPDLF and S-DROSS experiments, as described previously [24, 33, 34]. For POPE, the glycerol backbone and α -carbon peaks in INEPT spectra were assigned based on previously measured POPC spectra [33] and the β -carbon peak was assigned based on ^{13}C chemical shift table for amines available at <https://www.chem.wisc.edu/areas/reich/nmr/c13-data/cdata.htm> (Fig. S1). For POPG, the glycerol backbone peaks in INEPT spectra were assigned based on previously measured POPC spectra [33], while α and γ -carbon peaks **2. How were these assigned?** (Fig. S2). The numerical value of the β -carbon order parameter could not be determined, because its peak overlapped with the g_2 peak from glycerol backbone in POPG. However, the order parameter of β -carbon is expected to be clearly smaller than for g_2 based on previous ^2H NMR measurements [3, 6, 37]. Therefore, the beginning of the S-DROSS curve gives the sign for g_2 order parameter and end for β (Fig. S2 (E)). This is confirmed with SIMPSON calculations using negative value for g_2 and positive value for β order parameter (Fig. S3). **3. Details to be checked by Tiago.**

Molecular dynamics simulations

Molecular dynamics simulation data were collected using the Open Collaboration method [10], with the NMRLipids Project blog (nmrlipids.blogspot.fi) and GitHub repository (github.com/NMRLipids/NMRLipidsIVOtherHGs) as the communication platforms. The simulated systems of pure PE and PG bilayers without additional ions are listed in Tables S1 and S2, and lipid mixtures with additional ions in Table S4. Further simulation details are given in the SI, and the simulation data are indexed in a searchable database available at www.nmrlipids.fi, and in the NMRLipids/MATCH repository (github.com/NMRLipids/MATCH).

The C–H bond order parameters were calculated directly from the carbon and hydrogen positions using the definition

$$S_{\text{CH}} = \frac{1}{2} \langle 3 \cos^2 \theta - 1 \rangle, \quad (1)$$

where θ is the angle between the C–H bond and the membrane normal (taken to align with z , with bilayer periodicity in the xy -plane). Angular brackets denote average over all sampled configurations. The order parameters were first calculated averaging over time separately for each lipid in the system. The average and the standard error of the mean were then calculated over different lipids. Python programs that use the MDAnalysis library [38, 39] used for all atom simulations is available in Ref. 40 (`scripts/calcOrderParameters.py`). For united atom simulations, the trajectories with hydrogens having ideal geometry were constructed first using either `buildH` program [41] or (`scratch/opAAUA_prod.py`) in Ref. 40, and the order parameters were then calculated from these trajectories. This approach has been tested against trajectories with explicit hydrogens and the deviations in order parameters are small [41, 42].

4. BuildH program is now cited with a direct link to the GitHub repo. I think that a release to Zenodo would be nice in the final publication.

5. Maybe we should also shortly discuss here about the reasons for slight dependence of order parameter values on the method used to reconstruct hydrogens?

The ion number density profiles were calculated using the `gmx density` tool of the Gromacs software package [43].

Analysis of molecular dynamics simulation data

The big data set of MD simulations was analysed in the NMRLipids databank manner. Unique naming convention for lipid atoms in each force field was defined using the mapping files and analysis for all simulations indexed in NMRLipids databank manner were performed using python codes.

Analysis of lipid conformations bound to proteins

Dihedral angles of all available conformations in the PDB databank were calculated using the API access to the databank.

RESULTS AND DISCUSSION

Conformational ensembles of different lipid headgroups in bulk bilayer

To experimentally characterize the differences in lipid headgroup conformational ensembles in liquid bilayer phase, we measured the C-H bond order parameters magnitudes and signs from POPG and POPE bilayers. Order parameters for POPE are in good agreement with previous ^2H NMR experiments [36] and similar to our previous results for POPC [34]. In POPG, the β and g_2 carbons have similar chemical environment and their peaks overlap in the NMR spectra (Fig. 1 B). The signs of these order parameters were solved using SIMPSON simulations to interpret the S-DROSS experiments in similar fashion as we did previously for PS lipids [24]. The resulting order parameters are compared with our previously published results for POPC [33, 34] and POPS [24] in figure 1 D.

The most distinct order parameters are observed for PS and PG headgroups. In PS, the α -carbon order parameter exhibits significant forking and the β -carbon has more negative value than in other lipids. In PG headgroup, the β -carbon order parameter has positive sign in contrast to all the other lipids. Notably, this has not been observed in traditional ^2H NMR experiments, where only the absolute value of the order parameters are measured [3, 6, 37]. The glycerol backbone order parameters are similar for all the lipids, although they move slightly toward positive values (closer to zero) in the order $\text{PC} < \text{PE} < \text{PS} < \text{PG}$.

To characterize the differences in lipid headgroup conformational ensembles leading to the distinct order parameters in PS and PG lipids, we calculate the the distributions of heavy atom dihedral angles from CHARMM36 simulations. Among available simulation models, this force field has least problems in reproducing the experimental lipid headgroup and glycerol backbone order parameters in different lipids [10, 24] (Figs. S4 and S5). Importantly, it captures the experimentally observed distinct order parameters for PS and PG headgroups (Fig. ??). The dihedral distributions in figure 2 show significant similarity between different lipids for all the other bonds, except for the last two bonds in the headgroup end, $\text{O}_\alpha\text{-C}_\alpha$ and $\text{C}_\alpha\text{-C}_\beta$. These differences explaining the distinct order parameters of PS and PG headgroups with respect to the other lipids. The difference between PC and PE lipids in the $\text{O}_\alpha\text{-C}_\alpha$ bond dihedral may be an artefact because the β -carbon order parameter in PC is poorly reproduced by the CHARMM36 force field [10]. The differences between lipids are reflected also to the angle between headgroup dipole and membrane

normal, which decreases in the order of $\text{PG} > \text{PE} > \text{PC} > \text{PS}$ (Fig. 2).

The analysis of dihedral angle distributions reveal the free rotation of dihedral around phosphorus-oxygen bonds in all lipids as all possible angles are observed in the distributions. Results in figure ?? support the recently proposed models where this free rotation decouples the dynamics and conformational ensembles between acyl chains and headgroup in all lipids containing the phosphorus group [?]. However, some dihedral angles of phosphorus-oxygen bonds are less likely for PS, which possibly explains the more rigid headgroup structures proposed for PS lipids [1, 44].

In conclusion, all lipid headgroups sample very broad conformational ensembles in liquid lamellar phase. Despite the differences in dihedral distributions of two the last bonds at the headgroup end, leading to the distinct order parameters for PS and PG lipids, lipids with different headgroup sample dihedral angles within approximately same ranges. Altogether, our results suggest that lipid headgroups are very flexible thereby being able to adopt multiple conformations when interacting with proteins, ions or other biomolecules. Furthermore, approximately same conformations are present in liquid lamellar phase for different headgroups studied here, although the probability weight for the conformations are slightly different.

Lipid conformational ensembles in lipid bilayers with bound ions

Order parameters of α and β carbons in PC lipid headgroup are known to depend linearly on the incorporation of charged molecules into a lipid bilayer, which is explained by tilting of the headgroup dipole orientation [?]. Such changes have been observed upon addition of charged lipids, proteins, surfactants, drugs, or ions [?], but how charges affect the lipid conformational ensemble remains unknown.

The experimentally measured decrease of PC headgroup order parameters upon addition of cationic surfactants into a bilayer are well captured by CHARMM36 simulations in figure 3 A, suggesting that these simulations can be used to interpret how lipid headgroup conformational ensembles respond to the binding of positively charged into a membrane. Characterization of conformational ensembles using heavy atom dihedral angle distributions in figure 3 B reveal that choline region is essentially unchanged upon addition of charge. The major changes upon addition of charge are observed in dihedrals related to the phosphate oxygens, while small change is observed also in the $g_2\text{-}g_3$ bond in the glycerol backbone. This result is in line with the recently proposed model suggesting that the flexible phosphate enables the headgroup orient according to the charge accumulated into a membrane [?].

Headgroup order parameters of PC lipids respond similarly also to the addition of charged lipids in experiments [?]. To resolve the conformational ensembles of lipid headgroups also in biologically relevant mixtures, we compared the response

FIG. 1: Chemical structure, refocused-INEPT spectrum, 2D R-PDLF spectra, and S-DROSS data (from top to bottom) of **A)** POPE and **B)** POPG. **C)** Chemical structure of POPC and POPS. **D)** Headgroup and glycerol backbone order parameters from different experiments in lamellar liquid disordered phase. The values and signs for POPE (310 K) and POPG (298 K) measured in this work, and for POPS (298 K) [24] and POPC (300 K) [33, 34] previously using ^{13}C NMR. The literature values for DOPS with 0.1M of NaCl (303 K) [44], POPG with 10nM PIPES (298 K) [37], DPPG with 10mM PIPES and 100mM NaCl (314 K) [6], DPPE (341 K) [36], E.coliPE and E.coliPG (310 K) [3] are measured using ^2H NMR. The signs from ^{13}C NMR are used also for the literature values.

6. This is a sketch, needs a lot of polishing.

7.D) could be clarified as Fig. 2 in the NMRlipids IVps paper.

of headgroup order parameters in PC lipids to the addition of PE or PG (Fig. ??), as well as in PG lipids to the addition of PC (Fig. ??), between simulations and experiments. However, the accuracy of currently available force fields is not sufficient to capture the headgroup conformational ensembles in mixed membranes: The best performing force field for single component membranes, CHARMM36, overestimates the effect of PE to PC conformations and underestimates the response PC to the addition of anionic PG headgroup. Previously we explained similar result for PC/PS mixtures by overbinding of the sodium counterions [24].

In order to analyze how conformational ensemble of PC and PG lipids response to the bound ions, we compared the changes of headgroup order parameters in POPC:POPG (1:1) and (4:1) mixtures upon addition of CaCl_2 from different simulations to the experimental data available in the literature [37, 45] in figures 4 and S9. As in our previous studies [23, 24, 29], the calcium binding affinity to membranes is typically overestimated in simulations, except by CHARMM36 with the NBfix correction which underestimates the binding affinity, and the implicit inclusion of electronic polarizability improves the results. Lipid17ecc model

with the implicit inclusion of electronic polarizability gives the most realistic response of PC lipid headgroup order parameters to the binding of calcium. In this model, the main effect of calcium to the lipid conformational ensemble is the slight change of $\text{g}_3\text{-O}_{\text{g}_3}\text{-P-O}_\alpha$ dihedral distribution from trans state to eclipsed conformations (Fig. S12). This is in line with the changes observed in CHARMM36 simulations upon addition of charged surfactants (Fig. 3), despite the major differences in lipid headgroup conformational ensembles between these models without ions (Fig. 2 vs. Fig. S12).

Decrease in headgroup order parameters of PC lipids upon addition of charges is usually qualitatively captured in simulations despite the inaccuracies in lipid conformational ensembles [23], but situation with PS lipids is more complicated [24]. Here, Lipid17 and Slipids force fields correctly capture the PG β -carbon order parameter response to CaCl_2 in figure 4 even though the calcium binding affinity was overestimated. Heavy atom dihedral angle distributions calculated from these simulations suggest that also the headgroup glycerol conformations in PG are affected by calcium (Figs S13 and S14), in contrast to PC lipids where only conformations near phosphate were affected. On the other hand, the upward tilting of

FIG. 2: Results from CHARMM36 simulations demonstrating the differences in conformational ensembles between different lipids. **A)** Snapshots with overlaid C_β , C_α and O_α atoms and occurrence of different conformations. **B)** Headgroup and glycerol backbone region order parameters of different different lipids. **C)** Distributions of heavy atom dihedral angles of different lipids from CHARMM36 simulations. **D)** Distributions of P-N vector angle with respect to membrane normal.

8. This is a draft and requires quite a bit of polishing. More detailed discussion of this figure is in <https://github.com/NMRLipids/NMRLipidsIVPEandPG/issues/9>

the headgroup dipole is weaker in PG than in PC headgroup, possible due to the compensating effects from the changes in phosphate and glycerol regions. However, none of the simulations captures and calcium binding affinity and conformational ensemble of PG lipids simultaneously, and experimental data to evaluate the response of α -carbon order parameters to the added calcium in PG is not available. Therefore, more accurate force fields are required for the solid analysis of PG conformations ensembles in different ionic conditions.

Despite the limited capability of simulations to interpret

some experimental data due to the inaccuracies in force fields, we can conclude that the experimentally observed changes in headgroup order parameters upon addition of charges into bilayer arise from relatively small changes in conformational ensembles. These changes can be characterised by mild changes in dihedral angle distributions, rather than restriction of lipids into fixed conformations. Therefore, lipid headgroups remain in disordered state sampling large space of different conformations, thereby being able to interact with different molecules in various ways, also when charged

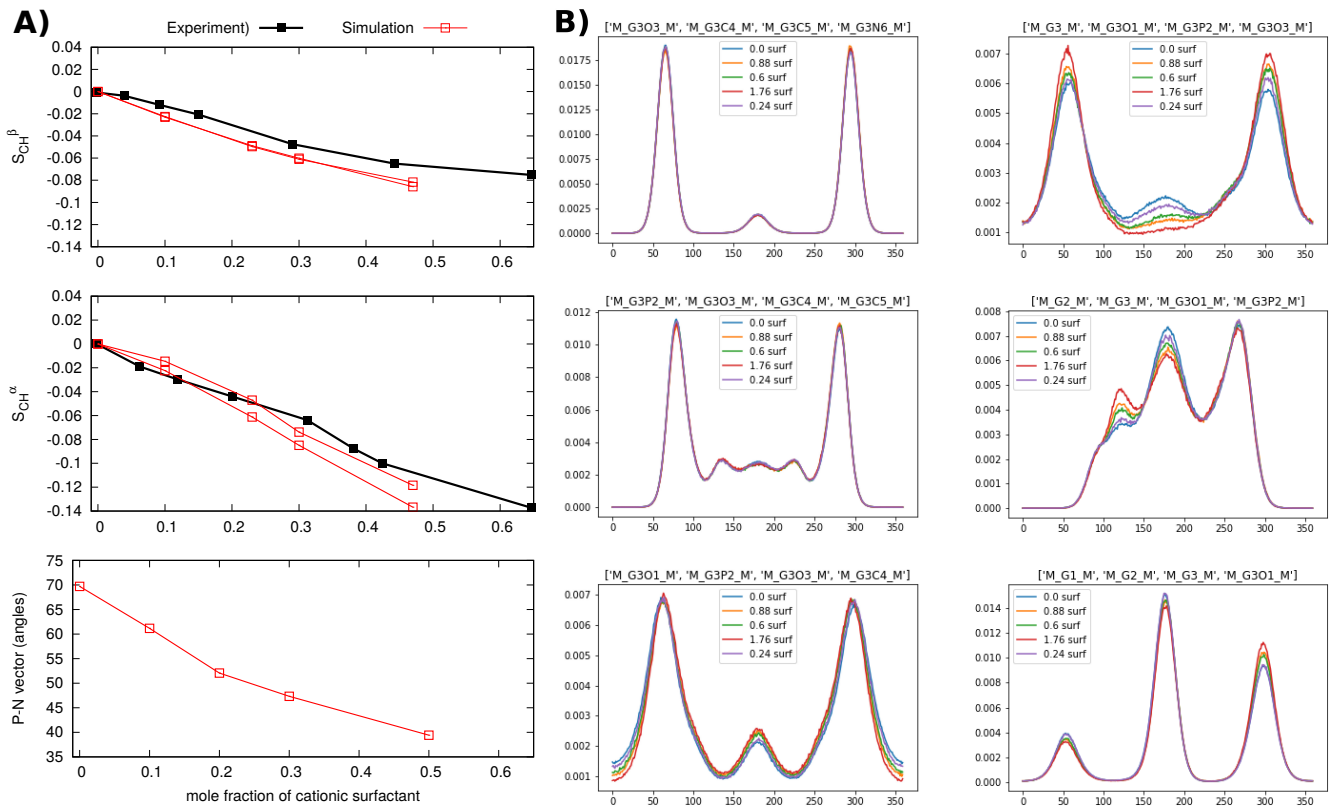

FIG. 3: **A)** Modulation of PC headgroup order parameters and P-N vector angle upon addition of cationic surfactant from CHARMM36 simulations compared with experimental data [?]. **B)** Changes in PC headgroup conformational ensembles upon increasing amount of positive charge in bilayer, characterized by the heavy atom dihedral distributions, from CHARMM36 simulations.

molecules are bound to membranes.

Protein bound lipid conformations

While our results in previous sections suggest that lipid headgroups sample large conformational space in liquid lamellar phase, lipids can bound to proteins in fixed conformations which can be then detected using crystallography or cryo-EM. Such protein bound lipid conformations are available within protein structures deposited in The Protein Data Bank (PDB) available at <http://www.rcsb.org/> [47]. With our criterias described in the methods, we found ?? conformations of PC lipids, ?? conformations of PE lipids, ?? conformations of PG lipids, and ?? conformations of PS lipids from PDB.

To analyze the relation of lipid headgroup conformational ensembles between liquid lamellar and protein bound states, we calculated the heavy atom dihedral angle distributions also from the protein conformations found from the PDB. The results in figure 5 do not reveal major differences between different lipid headgroups when bound to proteins. Some preference for trans state in $C_{\alpha}-C_{\beta}$ bond of PC lipids, and for positive angles in $O_{\alpha}-C_{\alpha}$ and $P-O_{\alpha}$ of PS lipids with respect to other lipids may be present in the data, but more statistics

is required for solid conclusions. Therefore, the differences in conformational ensembles between different lipids observed in liquid lamellar state are not clearly visible in the protein bound states.

Almost all dihedral angles are found from the protein bounds states for all dihedrals except for $P-O_{\alpha}-C_{\alpha}-C_{\beta}$ and $g_2-g_3-O_{g_3}-P$, which seem to avoid the cis conformations. The wide range of available dihedrals is similar to our results in liquid lamellar state, except for $O_{\alpha}-C_{\alpha}-C_{\beta}-C_{\gamma}$ and $g_1-g_2-g_3-O_{g_3}$ dihedrals which seem to be more restricted in the liquid lamellar phase (Fig. 2). This suggests that lipids compromise their preferred conformations when bound to proteins to minimize the intermolecular interactions with proteins.

CONCLUSIONS

We have measured the C-H bond order parameters with the signs for headgroup and glycerol backbone regions of the most most abundant biological phospholipids, PC, PE, PG and PS. Combining this experimental data with the large amount of simulation data collected using the NMRlipids open collaboration, we were able to resolve the differences between conformational ensembles of lipid headgroup leading to the differences observed in NMR experiments.

FIG. 4: Modulation of headgroup order parameters of POPC (*left*) and POPG (*right*) in POPC:POPG (1:1) mixture upon addition of CaCl_2 in 298 K temperature from experiments [37, 45] and simulations. The β -carbon order parameter of POPC (dashed line on top left) is not directly measured but calculated from empirical relation $\Delta S_\beta = 0.43 \Delta S_\alpha$ [46]. The changes with respect to the systems without CaCl_2 are shown for other data than for the α -carbon of POPG for which experimental order parameter is not available. Calcium density distributions are shown in figure S8.

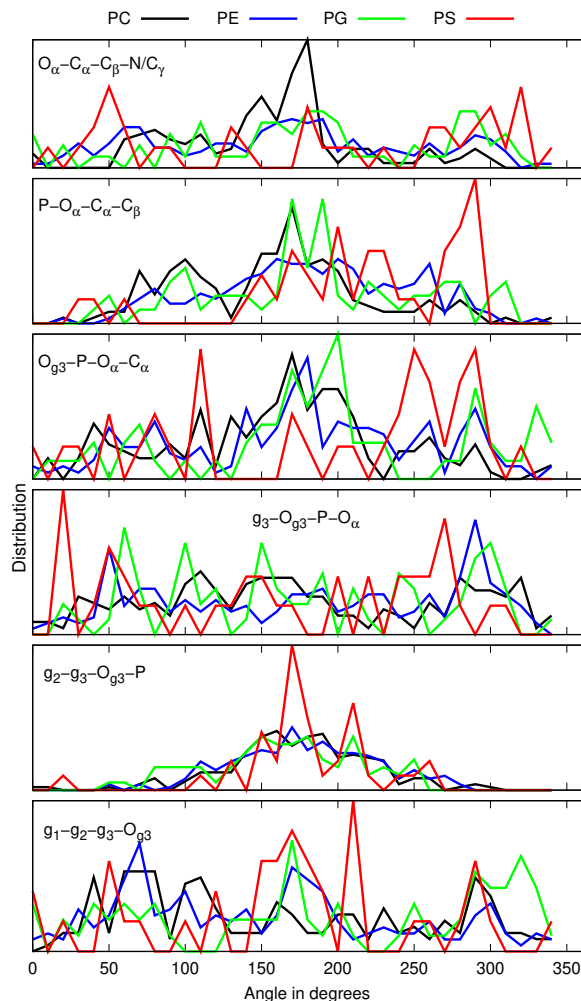

FIG. 5: Dihedral distributions from simulations and lipid structures in PDB.

Our results indicate that lipid headgroups are flexible and sample large conformational space in biologically relevant liquid lamellar state, also in membranes containing charged molecules, which have the largest affect on lipid headgroups in NMR experiments. Therefore, lipids can bind to proteins and other biomolecules in multiple different conformations, as indeed observed in the analysis of protein bound lipid conformations available from PDB. The weak correlation between lipid structures in liquid lamellar phase and protein bound state suggestst that the selective lipid binding to proteins is dominated by the intermolecular lipid-protein interactions, and the differences in conformational ensembles between different lipid types play only a minor role.

Our results pave the way to understand how lipids regulate membrane protein function. For example, the resolved lipid conformational ensembles in liquid lamellar phase and realistic MD simulations enables accurate analysis of lipid-protein interactions energetics. Furthermore, our results demonstrate how NMR data can be combined with the large amount of indexed MD simulation data to find the most realistic conforma-

tional ensembles of biomolecules in membrane environment. This paves the way toward standardized methods to resolve the quality evaluated conformational ensembles of disordered biomolecules in membrane environment. In the NMRlipids project we aim to build a general databank of quality evaluated conformational ensembles of lipids and other disordered biomolecules based primarily on MD simulations and NMR data.

ToDo

P.

1. Is this enough and correct, or should we repeat some methods from the NMRLipidsIVps paper? 2
2. How were these assigned? 2
3. Details to be checked by Tiago 2
4. BuildH program is now cited with a direct link to the GitHub repo. I think that a release to Zenodo would be nice in the final publication. 2
5. Maybe we should also shortly discuss here about the reasons for slight dependence of order parameter values on the method used to reconstruct hydrogens? 2
6. This is a sketch, needs a lot of polishing. 4
7. D) could be clarified as Fig. 2 in the NMRLipids IVps paper. 4
8. This is a draft and requires quite a bit of polishing. More detailed discussion of this figure is in <https://github.com/NMRLipids/NMRLipidsIVPEandPG/issues/9> 5
